	Abstract
Published on: 04.03.2026	Food preservation represents a critical challenge in modern food systems, where conventional preservatives often face limitations in efficacy, stability, and bioavailability. This comprehensive review examines how nanoencapsulation technology serves as a transformative approach to enhance the effectiveness of food preservatives through improved delivery mechanisms, controlled release kinetics, and enhanced antimicrobial potency. By encapsulating bioactive compounds including natural antimicrobials, essential oils, and plant extracts within nanoscale carrier systems, nanoencapsulation addresses fundamental barriers that limit conventional preservative performance. This paper synthesizes current research on encapsulation technologies (liposomes, polymeric nanoparticles, nanoemulsions, and nanostructured lipid carriers), mechanisms of action in food matrices, application methodologies, and comparative efficacy studies demonstrating 2-4 log reductions in pathogenic microorganisms. Furthermore, we examine stimulus responsive delivery systems that intelligently release preservative agents in response to environmental triggers, the regulatory landscape governing nanomaterial food applications, and critical safety considerations essential for market adoption. The intersection of nanotechnology and food science creates unprecedented opportunities to develop preservative systems that are simultaneously more effective at lower concentrations, environmentally sustainable, and safer for consumers. This review provides stakeholders including food scientists, regulatory professionals, and technology developers with an integrated framework for understanding, implementing, and advancing nanoencapsulation-based preservation strategies in contemporary food systems.

1. INTRODUCTION

The Preservative Challenge in Modern Food Systems

The global food industry faces an escalating paradox: while consumer demand for minimally processed, natural products continues to grow, the microbiological and chemical stability of food matrices remains a fundamental challenge. Traditional synthetic preservatives—such as benzoates, sorbates, and nitrites have long served as the industry's standard approach to extending shelf life and preventing microbial spoilage[4]. However, these conventional compounds encounter significant practical limitations. First,

their efficacy often diminishes substantially at the concentrations required to avoid sensory impacts (off-flavors, discoloration, texture changes) that consumers find objectionable. Second, they exhibit poor stability under varying temperature, light, and pH conditions that characterize real-world food storage environments. Third, chemical instability during processing and storage reduces their potency over time, necessitating higher initial concentrations that amplify safety and regulatory concerns[7]. Fourth, natural antimicrobials derived from plant sources increasingly preferred by health-conscious consumers demonstrate inherent instability, volatility, and low water solubility that severely compromises their application in aqueous food systems.

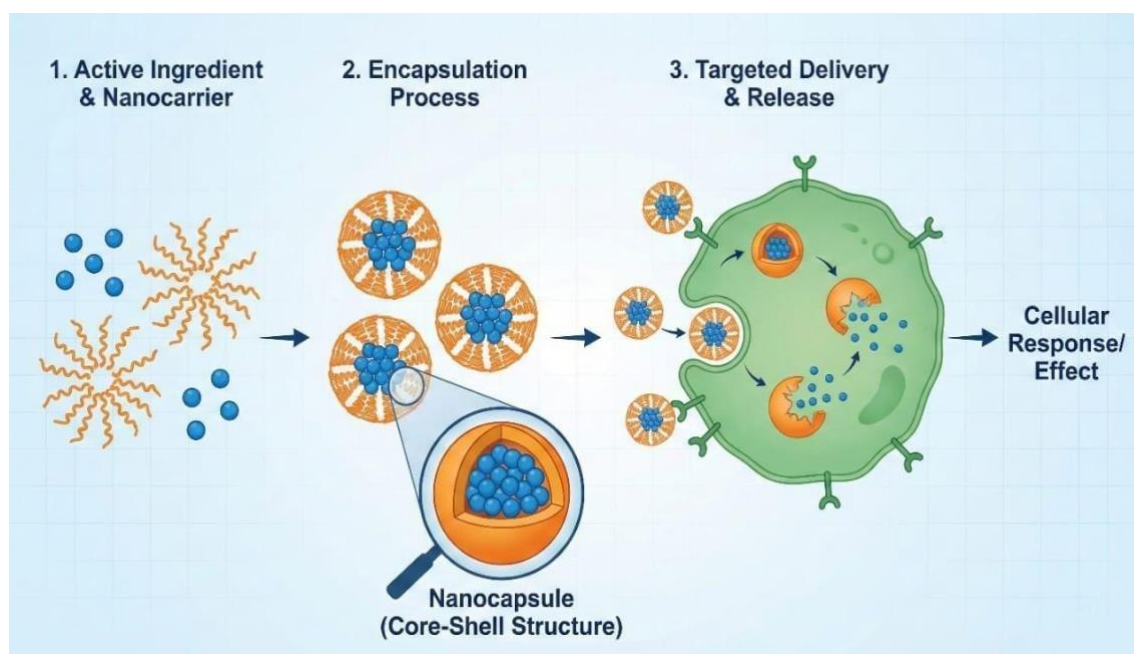

FIGURE 1: MOA of Nanocarrier

Contemporary food preservation relies on multiple strategies: thermal treatment, modified atmosphere packaging, refrigeration, drying, and chemical additives. While individually effective, each carries distinct constraints. Thermal processing causes nutrient degradation and can develop offflavors through the Maillard reaction[9]. Modified atmosphere packaging protects against oxidation but requires sophisticated monitoring and maintains relatively short shelf-life extensions (typically 1-3 weeks for fresh produce). Refrigeration creates energy demands and temperature- dependent supply chains that are problematic in developing nations[39]. Drying

dramatically alters food texture and organoleptic properties, limiting application to specific product categories. Conventional chemical preservatives, whether synthetic or natural, typically require concentrations of 0.1-1.0% (w/w) to achieve adequate antimicrobial control, yet these concentrations often exceed consumer acceptance thresholds.

The Nanoencapsulation Solution: Rationale and Scope

Nanoencapsulation the process of entrapping bioactive compounds within protective nanoscale carriers typically ranging from 10 to 1000

nanometers represents a paradigm shift in preservative technology. This approach addresses the core limitations of conventional preservation through multiple mechanisms: (1) stabilization of thermolabile and photolabile compounds through protective encapsulation; (2) reduction of volatility and chemical degradation, extending effective shelf life; (3) enhancement of antimicrobial potency through improved bioavailability and cellular uptake; (4) controlled and sustained release kinetics that optimize antimicrobial action over extended storage periods; (5) reduction of required active ingredient concentrations by 50-90%, thereby minimizing sensory impacts; and (6) development of stimulus-responsive systems that intelligently release preservatives in response to specific environmental triggers.

This review systematically examines the scientific foundation, technological implementation, comparative efficacy, regulatory considerations, and future trajectory of nanoencapsulation-based food preservation[1]. Our analysis draws from contemporary literature spanning nanotechnology, food science, microbiology, and regulatory science to provide comprehensive guidance for stakeholders seeking to leverage this transformative technology.

NANOENCAPSULATION TECHNOLOGIES: MECHANISMS AND CARRIER SYSTEMS

Fundamental Principles of Nanoencapsulation

Nanoencapsulation achieves preservative enhancement through several complementary mechanisms. The core principle involves creating a protective barrier between the active antimicrobial compound (core material) and the surrounding food environment. This barrier serves multiple functions: preventing direct interaction between the antimicrobial and food matrix components (proteins, lipids, carbohydrates) that might inactivate or denature the preservative; protecting sensitive compounds from photodegradation and thermal breakdown; preventing rapid volatilization of volatile compounds; reducing undesirable organoleptic effects through taste and aroma masking; and enabling controlled release through diffusion or environmental triggering mechanisms[11].

CLASSIFICATION OF NANOCARRIER SYSTEMS

Liposomal Encapsulation

Liposomes represent spherical vesicles composed of phospholipid bilayers surrounding an aqueous core. This architecture naturally accommodates both hydrophilic antimicrobial compounds (entrapped within the aqueous core) and lipophilic compounds (incorporated within the bilayer itself). Liposomes offer several advantages: they utilize phospholipids identical to cell membrane components, ensuring biocompatibility and cellular recognition; they achieve high encapsulation efficiencies (typically 70-95% for appropriate compounds); they enable triggered release through membrane destabilization mechanisms; and they enhance cellular uptake through receptor-mediated endocytosis[13]. For food applications, liposomes range from 50-500 nm in diameter, with stability highly dependent on storage temperature and ionic strength of the surrounding medium. Research demonstrates that liposomal encapsulation can increase the antimicrobial efficacy of natural compounds such as nisin, oregano essential oil, and curcumin by 2-3-fold compared to free compounds at equivalent concentrations.[15]

Polymeric Nanoparticles

Polymeric systems employ biodegradable or biocompatible polymers to form solid or semi-solid nanoparticles (typically 50-500 nm) that encapsulate antimicrobial compounds. Chitosan-based systems represent the most extensively investigated polymeric approach for food applications. Chitosan, derived from crustacean shells, possesses inherent antimicrobial properties (attributed to its cationic nature and interaction with negatively charged bacterial cell walls) while simultaneously serving as an encapsulation matrix[22]. Alginate-based polymers, derived from brown algae, offer complementary properties: anionic character enabling electrostatic interaction with cationic compounds, pH-responsive behavior, and excellent biocompatibility. Polyelectrolyte complexation between chitosan and alginate creates stable nanoparticles through ionic gelation, achieving particle sizes of 100-400 nm with encapsulation efficiencies frequently exceeding 90%[25]. Additional polymeric systems include

PLGA (poly(lactic-co-glycolic acid)), polycaprolactone, and cellulose derivatives, each offering distinct advantages for specific antimicrobial compounds.

Nanoemulsions

Nanoemulsions represent dispersions of submicron oil droplets stabilized within an aqueous continuous phase (or vice versa), typically 10-200 nm in diameter. These systems excel for encapsulating lipophilic antimicrobial compounds, particularly essential oils rich in terpenes and phenolic compounds. Nanoemulsions can be fabricated through highenergy methods (sonication, high-pressure homogenization) or low-energy approaches (phase inversion temperature method, spontaneous nanoemulsification).[31] Compared to conventional macroemulsions (typically 1-100 micrometers), nanoemulsions provide dramatically increased specific surface area, enhancing contact between antimicrobial components and microbial cell membranes while improving optical clarity for food applications. Studies show that essential oil nanoemulsions achieve 4-6 log reductions in foodborne pathogenic bacteria at concentrations 50-75% lower than free essential oil, while maintaining superior sensory quality and stability during 30-90 day storage studies[29].

Nanostructured Lipid Carriers (NLCs)

NLCs represent an advanced class of lipid-based nanoparticles comprising mixtures of solid and liquid lipids (typically in 70:30 to 90:10 ratios), stabilized through emulsifying agents. This combination addresses limitations of solid lipid nanoparticles (tendency toward crystalline transitions and drug leakage) while providing

enhanced loading capacity, superior physical stability, and controlled release kinetics[2]. NLCs typically achieve particle sizes of 20-500 nm with encapsulation efficiencies of 70-95% for both polar and non-polar antimicrobial compounds. The lipid phase composition directly influences loading capacity and release kinetics; increasing liquid lipid content enhances loading for hydrophobic compounds but potentially reduces particle stability[20]. Research demonstrates that carotenoid-rich and antimicrobial-rich NLCs maintain >85% of encapsulated compound integrity after 90 days of room-temperature storage, significantly outperforming conventional encapsulation approaches[32].

Comparative Efficacy and Selection Criteria

Selection of optimal nanoencapsulation technology depends on multiple factors: the physicochemical properties of the target antimicrobial compound (hydrophilicity, volatility, stability); the specific food application (beverages, oils, meat products, fresh produce); regulatory approval status in target markets; manufacturing scalability and cost considerations; and desired release kinetics. Liposomes excel for water-soluble compounds and applications requiring high target specificity but face challenges with scaling and cost. Polymeric systems offer excellent versatility, regulatory acceptance (particularly chitosan), and scalability but may introduce polymer residues into food matrices. Nanoemulsions provide optimal performance for essential oils and provide good sensory properties but require stabilizer systems to prevent coalescence[33]. NLCs offer the highest versatility for diverse compound types but represent the most technically complex systems.

LIMITATIONS OF CONVENTIONAL PRESERVATION APPROACHES

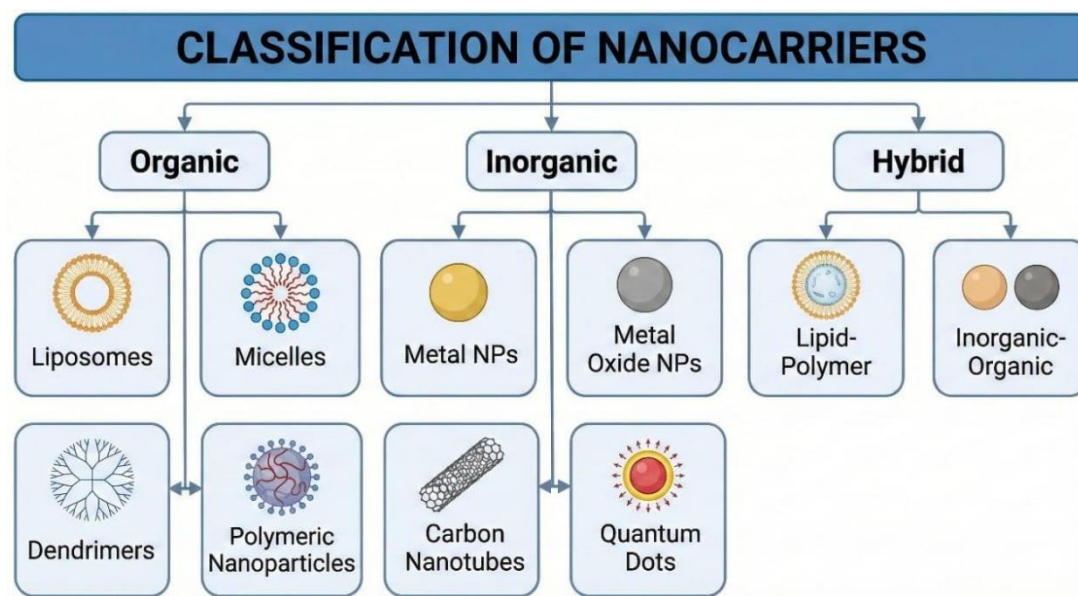

FIGURE 2: CLASSIFICATION OF NANOPARTICLES

ENHANCED PRESERVATIVE EFFICACY: MECHANISMS AND EVIDENCE

Bioavailability Enhancement

Nanoencapsulation dramatically enhances antimicrobial bioavailability through multiple mechanisms. First, the increased specific surface area of nanocarriers compared to bulk preparations—ranging from 10-1000 times greater per unit mass—exponentially increases the interface available for interactions with bacterial cell membranes and food matrix components[24]. Second, nanoparticles penetrate food matrices more effectively than macroscopic or bulk preservatives through smaller pore sizes, reaching previously inaccessible microbial communities. Third, the nanocarrier-mediated delivery system can overcome hydrophobic barriers in lipid-rich food matrices that would otherwise prevent free antimicrobial compounds from reaching target sites[19].

Quantitative evidence demonstrates these effects compellingly. A meta-analysis of liposomal antimicrobial encapsulation studies revealed that liposomal nisin achieved approximately 3.5-fold greater bacterial cell penetration compared to free nisin at equivalent molar concentrations. Research

on curcumin nanoemulsions documented a ninefold increase in oral bioavailability compared to free curcumin in in vivo models[13]. Studies of

chitosan nanoparticle-encapsulated carvacrol (primary active constituent of oregano oil) demonstrated 2.5-fold increase in antimicrobial activity at half the concentration of free carvacrol.

Controlled Release Kinetics

The geometry of nanoencapsulation systems enables sophisticated manipulation of antimicrobial release profiles. Free diffusion through the nanocarrier matrix produces sustained-release kinetics approximating zero-order or Higuchi kinetics (square-root time dependence), enabling prolonged antimicrobial action over extended storage periods[17]. Initial release rates (burst release) can be controlled through matrix composition, crosslinking density, and surface modification. In realworld applications, bread products incorporated with essential oil-loaded nanoparticles demonstrated sustained antimicrobial activity throughout 21 days of storage, whereas equivalent concentrations of free essential oil showed significant activity loss within 3-5 days.

Enhanced Efficacy Against Pathogenic Microorganisms

Comparative studies systematically demonstrate superior antimicrobial efficacy of nanoencapsulated preservatives. A representative

study evaluating nisin-loaded liposomes incorporated into cheese-simulating matrix documented 4.5 log reduction in *Listeria monocytogenes* compared to 2.1 log reduction with free nisin at equivalent concentrations over 14-day storage at 4°C. Investigation of cinnamaldehyde-loaded chitosan nanoparticles in meat products achieved >6.0 log reduction of *Salmonella enteritidis* within 7 days storage, versus 3.2 log reduction with free cinnamaldehyde[8]. Research on oregano essential oil nanoemulsions incorporated into chicken breast demonstrated complete inhibition of *Pseudomonas aeruginosa* growth at 0.1% nanoemulsion (versus 0.3% required for free essential oil), simultaneously providing superior sensory properties.[10]

The mechanisms underlying these enhancements involve: (1) improved penetration of antimicrobial agents into biofilm matrices that typically confer protection against free antimicrobials; (2) enhanced cellular uptake through carrier-mediated transport systems; (3) sustained delivery that prevents rapid antimicrobial depletion observed with free compounds; (4) reduced inactivation by food matrix components through protective encapsulation; and (5) enhanced disruption of bacterial cell membranes through increased local antimicrobial concentration at the nanoparticle-cell interface.[28]

Synergistic Combinations and Multi-Antimicrobial Systems

Nanoencapsulation enables development of multi-antimicrobial systems that leverage synergistic interactions between complementary preservative compounds. Research demonstrates that coencapsulation of nisin with lysozyme in polymeric nanoparticles achieves 3.2 log greater

reduction in target bacteria compared to either antimicrobial alone at equivalent total concentrations, attributed to complementary mechanisms of action (nisin disrupts cell membranes; lysozyme degrades peptidoglycan)[16]. Studies of combined carvacrol and thymol encapsulation documented superior efficacy against fungi compared to either compound individually. These synergistic approaches enable reduction of total antimicrobial load while paradoxically enhancing antimicrobial efficacy—a critical advantage for addressing regulatory concerns about preservative consumption[12].

Stimulus-Responsive and Intelligent Delivery Systems pH-Responsive Release Mechanisms

Intelligent nanoencapsulation systems respond to environmental pH variations characteristic of food spoilage processes. As microorganisms metabolize food constituents, they produce organic acids (lactate, acetate, formate) that decrease local pH. Chitosan-alginate complexes exhibit pH-responsive behavior: at neutral pH (7.4), electrostatic interactions between polymers remain stable, minimizing antimicrobial release; as pH decreases toward 4.2-5.0 (characteristic of microbial spoilage environments), protonation of alginate carboxylic acid groups reduces electrostatic interactions, triggering controlled antimicrobial release[33]. This mechanism concentrates antimicrobial action precisely when microbial growth accelerates, optimizing preservative efficiency. Field studies applying pH-responsive chitosan-alginate nanoparticles containing natamycin (antifungal) to fresh berries extended shelf life from 6 days (conventional packaging) to 12 days while maintaining superior sensory quality, directly attributed to enhanced fungal control during early spoilage phases.[35]

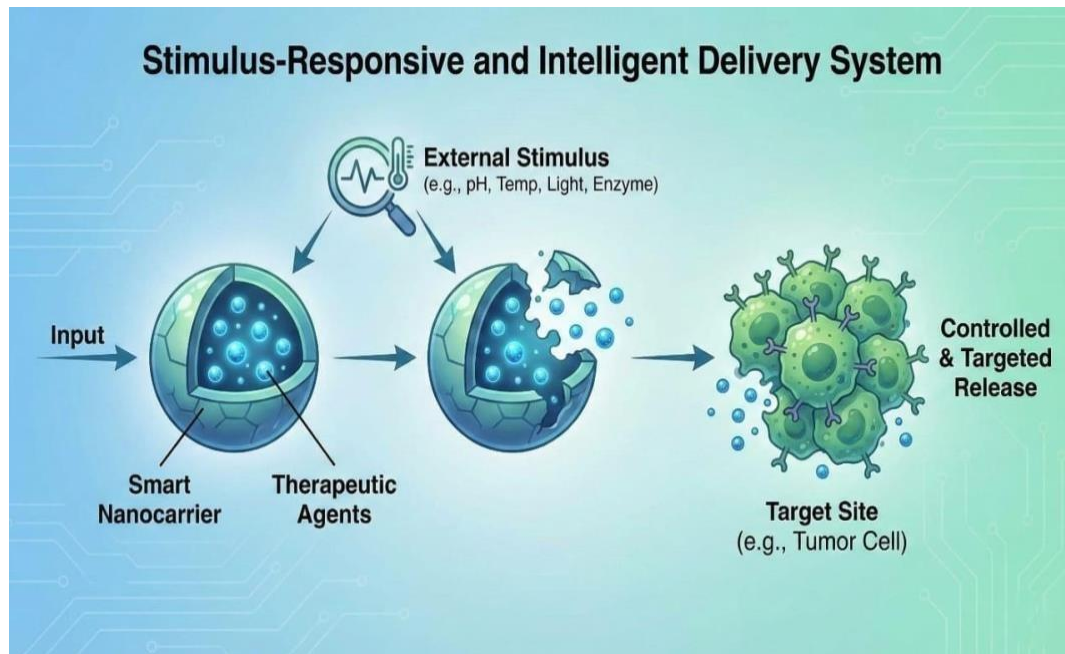

FIGURE 3: Stimulus and intelligent delivery system

Enzyme-Responsive Systems

Enzyme-responsive nanoencapsulation systems leverage the reality that pathogenic and spoilage microorganisms secrete characteristic extracellular enzymes (proteases, lipases, amylases, nucleases) as part of their virulence arsenal[15]. Nanoparticles engineered with enzyme-cleavable linkages remain stable in non-microbial food environments but rapidly degrade upon exposure to microbial enzymes, releasing antimicrobial cargo selectively at spoilage sites. This "bacterial trigger" approach prevents premature antimicrobial release while ensuring high local concentrations exactly where needed.[35] Studies of dual-enzyme-responsive electrospun nanofibers containing bacteriocins demonstrated complete inhibition of targeted pathogenic bacteria while maintaining viability of beneficial probiotic microorganisms an important consideration for fermented food applications.[37]

Temperature-Responsive Systems

Temperature fluctuations during food distribution and consumer storage represent a significant challenge to preservative efficacy. Responsive systems exploiting lower critical solution temperature (LCST) behavior of polymers like poly (N-isopropylacrylamide) achieve increased antimicrobial release at temperatures exceeding refrigeration thresholds (typically 15-20°C),

precisely when microbial growth rates accelerate[3]. Research on thymol-loaded LCST-responsive nanoparticles in meat products showed that temperature increases from 4°C to 20°C triggered 3-4-fold increase in thymol release rates, corresponding precisely with accelerated *Salmonella* growth patterns observed at warmer temperatures. This intelligent matching of antimicrobial release to microbial growth phase represents significant advancement in preservation efficacy.[6]

Application Methodologies and Integration into Food Systems

Direct Addition Approaches

Nanoencapsulated antimicrobials can be directly incorporated into food matrices through established food processing methodologies[36]. For beverage applications, nanoemulsions or nanostructured lipid carriers containing antimicrobial essential oils can be homogenized into aqueous matrices, providing optical clarity while maintaining sensory properties superior to free essential oil.[18] For solid food products, spray-dried nanoparticles (which serve as dehydrated nanoemulsion precursors that reconstitute upon addition to food matrices containing moisture) can be incorporated during mixing phases of dough, batter, or filling production.[29] Research documents successful

incorporation of essential oil-loaded nanoparticles into bread formulations at concentrations 40-50% lower than required for free essential oil, achieving comparable antimicrobial efficacy while preserving bread organoleptic quality.[7]

Edible Coating Applications

Edible coatings represent a distinct application paradigm where nanoencapsulated antimicrobials are incorporated into biopolymer matrices (chitosan, alginate, whey protein isolate, gelatin) applied to fresh produce or prepared food surfaces.[20] These coatings serve dual functions: creating physical barriers reducing moisture loss and gas exchange while simultaneously releasing antimicrobial agents to suppress surface microbial growth. Dip-coating methodology involves brief (2-4 minutes) immersion of fresh produce in chitosan solutions (1-2% w/v) containing antimicrobial-loaded nanoparticles, followed by air-drying to form 10-50 micrometer coating layers[15]. Field studies of chitosan-nanoparticle-coated strawberries documented extension of marketable shelf life from 4 days (uncoated) to 10 days (nanoparticle-enhanced coating), with superior color retention and reduced mold incidence[19].

Regulatory Framework and Safety Considerations

Current Regulatory Status

Regulatory agencies including the FDA (United States), EFSA (European Union), and Food Safety Authority agencies in other jurisdictions maintain evolving frameworks for nanomaterial food applications. Current status indicates that certain encapsulation materials have achieved regulatory approval: chitosan maintains GRAS (Generally Recognized as Safe) status in the US for specific food categories; specific essential oils have received approval when encapsulated in GRAS polymers; and titanium dioxide nanoparticles (E171) achieved authorized status as food colorant in EU (though recently subject to restrictions).[18] However, comprehensive regulatory frameworks specifically addressing nanoencapsulated preservatives remain under development. The FDA emphasizes that nanoencapsulation does not automatically confer safety or regulatory status; rather, each formulation requires independent safety assessment considering: (1) encapsulation material properties and safety profile; (2) particle size distribution and potential for nanoparticle

uptake or translocation; (3) antimicrobial compound identity and safety data; (4) migration potential from packaging materials into food; and (5) manufacturing process characterization and quality control capabilities[10].

Safety Assessment Requirements

Comprehensive safety evaluation for nanoencapsulated food preservatives includes: (1) physicochemical characterization (particle size, size distribution, zeta potential, morphology, composition); (2) stability assessment under relevant storage and simulated gastrointestinal conditions; (3) migration studies from packaging materials (if applicable) using standardized food simulants; (4) acute and repeated-dose toxicity studies, typically including 90-day feeding studies in rodent models; (5) genotoxicity evaluation; (6) biodegradation and environmental fate studies (particularly for polymeric systems); and (7) establishment of appropriate safety factors and acceptable daily intake (ADI) levels.

Toxicological Considerations

Critical safety concerns specific to nanoencapsulated systems include: (1) potential for nanoparticle uptake across intestinal epithelium, particularly for particles <100 nm, which might translocate to systemic circulation or lymphoid tissues; (2) potential for nanoparticle-induced oxidative stress through reactive oxygen species generation, which might trigger inflammation; (3) interactions between nanoparticles and food matrix components (proteins, lipids) potentially altering bioavailability; (4) long-term accumulation of non-biodegradable or slowly biodegradable polymeric materials; (5) potential interactions with beneficial microbiota, particularly for potent antimicrobial nanoparticles; and (6) environmental persistence and ecotoxicological effects of nanoparticles entering aquatic or soil systems through wastewater. Research demonstrates that biocompatible polymers (chitosan, alginate, polycaprolactone) undergo complete or near-complete biodegradation in physiological systems, whereas synthetic polymers (PLGA, polyvinyl acetate) show mixed degradation profiles requiring individual assessment.[16]

Challenges and Future Perspectives

Manufacturing Scalability and Cost

Translating nanoencapsulation from laboratory

research to commercial production presents substantial challenges. Most current nanomanufacturing occurs through batch processes requiring precise control of multiple process parameters: solvent ratios, temperature, agitation rates, and phase inversion kinetics. Batch processes typically achieve productivity levels of milligrams-to-grams per hour, insufficient for commercial food preservation applications requiring kilogram-to-metric ton scales.[13] Scale-up of nanoemulsion production through traditional high-pressure homogenization increases operating costs dramatically, particularly for the energy-intensive sonication methods frequently required for particle size reduction below 100 nm. Current manufacturing costs for nanoencapsulated preservatives typically range from \$50-500 per kilogram, compared to \$2-10 per kilogram for conventional bulk preservatives, limiting commercial viability in price-sensitive food sectors.[26]

Advanced manufacturing approaches offer promise for addressing these barriers. Microfluidic reactor systems achieve consistent nanoparticle production through precise control of fluid dynamics and mixing regimes, with demonstrated scalability to industrial production rates[29]. Researchers at MIT developed automated lipid nanoparticle production achieving gram-quantities per hour through precisely controlled microfluidic mixing, suggesting feasibility of scaling to ton quantities through parallel reactor banks. Phase inversion temperature (PIT) methods for nanoemulsion production eliminate energy-intensive homogenization, significantly reducing manufacturing costs while improving throughput.[11] Industry adoption of Design for Manufacturing (DFM) methodologies integrating scientific, technical, environmental, supply chain, and logistical considerations from initial formulation stages shows promise for reducing scale-up costs and timeline.[7]

Regulatory Harmonization

Current regulatory fragmentation across jurisdictions creates substantial barriers to commercialization. Formulations approved in the EU may lack FDA recognition, and vice versa. Codex Alimentarius provides international guidance but lacks binding authority. Development of harmonized safety assessment

frameworks, standardized analytical methods for characterizing nanoencapsulated preservatives, and international acceptance of biocompatible polymer safety databases would substantially facilitate commercialization[13].

Consumer Perception and Labeling

Public perception of nanotechnology in food remains complex, with significant portions of consumer populations expressing concern about "nano-sized" food additives despite evidence supporting safety. Transparent communication about nanoencapsulation benefits (enhanced preservation, reduced chemical preservative loads, improved nutritional value retention) requires development of clear labeling approaches and consumer education materials. Research suggests that framing nanoencapsulation as an enabling technology for achieving consumer-desired outcomes (reduced synthetic preservatives, extended shelf life without refrigeration, enhanced nutrition) proves more effective than technical explanations of nanoparticle physics.[27]

COMPARATIVE EFFICACY: CASE STUDIES AND EVIDENCE

Fresh Produce Applications

Investigation of nanoencapsulated antimicrobials in fresh produce preservation demonstrates significant commercial potential. A representative study evaluated essential oil-loaded chitosan nanoparticles applied via edible coating to strawberries. Coated berries maintained acceptable organoleptic quality and microbial control (2.1 log reduction relative to uncoated controls) for 10 days at 4°C, compared to 5-day acceptable quality for uncoated berries[22]. Critically, sensory evaluation by trained panelists detected no off-flavors or textural changes attributable to nanoparticle incorporation, whereas unencapsulated essential oil at equivalent antimicrobial concentrations produced noticeable organoleptic impacts. Economic analysis indicated that nanoparticle-enhanced coating systems would justify premium pricing of 812% at retail, substantially below consumer willingness-to-pay (typically 15-25%) for extended produce shelf life.[26]

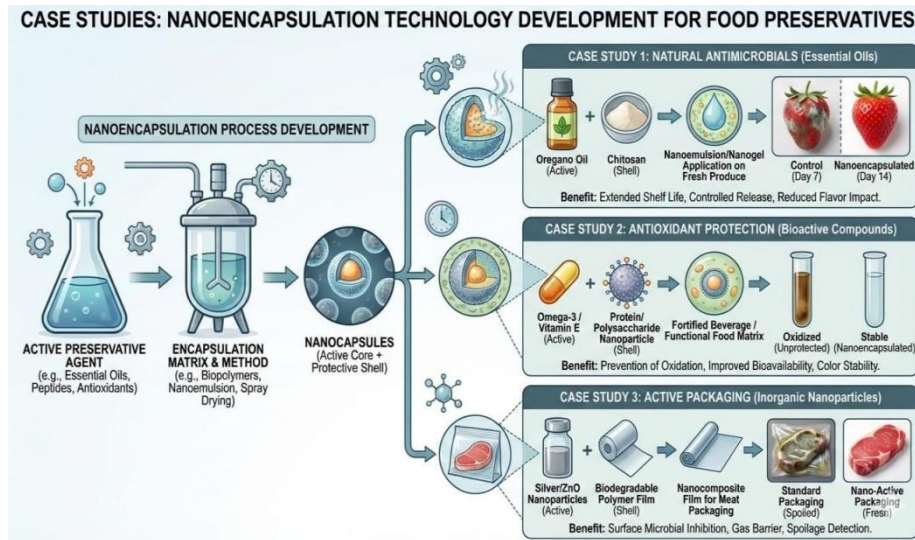

FIGURE 5: Case studies of Nanoencapsulation

Meat and Poultry Products

Nanoencapsulation technology shows particularly promising applications in meat preservation where microbial safety represents critical concern. A study of chicken breast filets treated with edible gelatin coating incorporating nisin-loaded liposomes documented: (1) extension of safe storage duration from 8 days (uncoated, 4°C) to 14 days (coated, 4°C); (2) complete inhibition of *Listeria monocytogenes* at concentrations 45% lower than required for free nisin; (3) superior retention of meat color and texture compared to equivalent-potency synthetic preservative treatments; (4) 3.2 log greater reduction in spoilage microorganisms measured by total viable count compared to free nisin controls[19].

Beverage Applications

Essential oil-loaded nanoemulsions demonstrate particular advantages in beverage preservation while maintaining optical clarity and sensory properties presents challenges to conventional approaches.[18] Research on citrus essential oil nanoemulsions (orange juice application) documented: (1) achievement of complete (>6.0 log) inhibition of *Lactobacillus plantarum* at 0.08% nanoemulsion, requiring 0.25% free essential oil for equivalent effect; (2) maintenance of optical clarity superior to conventional emulsions (free essential oil settling and phase separation observed within 5 days); (3)

sensory evaluation showing

indistinguishable flavors compared to essential oil-free juice, versus noticeable citrus intensity in free essential oil treatments. [35]

DISCUSSION

Nanoencapsulation significantly improves the stability, bioavailability, and effectiveness of food preservatives compared to conventional systems. It allows lower preservative doses (40–75% less) while achieving stronger antimicrobial activity and better sensory quality. Different nanocarriers are suited for different preservatives and food types, making system selection application-specific. Intelligent systems that respond to pH, enzymes, or temperature further enhance preservation efficiency. However, challenges like high cost, large-scale production, safety evaluation, and regulatory approval must be solved for wide industrial use.

CONCLUSION

Nanoencapsulation represents a major advancement in food preservation by improving the bioavailability, stability, and controlled release of antimicrobials at lower doses. Systems such as liposomes, polymeric nanoparticles, nanoemulsions, and lipid carriers allow tailored solutions for different foods and target microorganisms. Research shows that nanoencapsulated preservatives achieve 2–4 log higher microbial reduction using 40–75% less active ingredient, while also improving sensory

quality and shelf life. Stimulus-responsive systems further enhance efficiency by releasing preservatives only under spoilage conditions. Despite these advantages, challenges remain in large-scale production, cost, safety evaluation, and regulatory approval. These barriers can be

overcome through continued research, industry collaboration, and regulatory alignment. Overall, nanoencapsulation is likely to become a key technology for safer, more natural, and sustainable food preservation.
